ABSTRACT

Context. The nature and evolutionary properties of the faint radio population, responsible for the steepening observed in the 1.4 GHz source counts below 1 mJy, are not yet entirely clear. Radio spectral indices may help to constrain the origin of the radio emission in such faint radio sources and may be fundamental in understanding eventual links to the optical light.

Aims. We study the spectral index behaviour of sources that were found in the 1.4 GHz ATESP survey (Prandoni et al. 2000a,b), considering that the ATESP is one of the most extensive sub-mJy surveys existing at present.

Methods. Using the Australia Telescope Compact Array we observed at 5 GHz part of the region covered by the sub-mJy ATESP survey. In particular we imaged a one square degree area for which deep optical imaging in UBVR_{IJK} is available. In this paper we present the 5 GHz survey and source catalogue, we derive the 5 GHz source counts and we discuss the 1.4–5 GHz spectral index properties of the ATESP sources. The analysis of the optical properties of the sample will be the subject of a following paper.

Results. The 5 GHz survey has produced a catalogue of 111 radio sources, complete down to a (6σ) limit $S_{lim}(5\text{ GHz}) \sim 0.4\text{ mJy}$. We take advantage of the better spatial resolution at 5 GHz ($\sim 2''$ compared to $\sim 8''$ at 1.4 GHz) to infer radio source structures and sizes. The 5 GHz source counts derived by the present sample are consistent with those reported in the literature, but improve significantly the statistics in the flux range $0.4 \lesssim S_{5\text{ GHz}} \lesssim 1\text{ mJy}$. The ATESP sources show a flattening of the 1.4–5 GHz spectral index with decreasing flux density, which is particularly significant for the 5 GHz selected sample. Such a flattening confirms previous results coming from smaller samples and is consistent with a flattening of the 5 GHz source counts occurring at fluxes $\lesssim 0.5\text{ mJy}$.

1. Introduction

One of the most debated issues about the sub-mJy radio sources, responsible for the steepening of the 1.4 GHz source counts (Condon 1984, Windhorst et al. 1990), is the origin of their radio emission. Understanding whether the dominant triggering process is star formation or nuclear activity has important implications on the study of the star formation/black hole accretion history with radio-selected samples.

However, despite the extensive work done in the last decade, the nature and the evolutionary properties of the faint

radio population are not yet entirely clear. Today we know that the sub-mJy population is a mixture of different classes of objects (low-luminosity/high- z AGNs, star-forming galaxies, normal elliptical and spiral galaxies), with star-forming galaxies dominating the microJy (μJy) population (see e.g. Richards et al. 1999), and early-type galaxies and AGNs being more important at sub-mJy and mJy fluxes (Gruppioni et al. 1999; Georgakakis et al. 1999; Magliocchetti et al. 2000; Prandoni et al. 2001b). On the other hand, the relative fractions of the different types of objects are still quite uncertain, and very little is known about the role played by the cosmological evolution of the different classes of objects. Conclusions about the faint radio population are, in fact, limited by the incompleteness of op-

tical identification and spectroscopy, since faint radio sources have usually very faint optical counterparts. Clearly very deep ($R > 25$) optical follow-up for reasonably large deep radio samples are critical if we want to probe such radio source populations.

Also important may be multi-frequency radio observations: radio spectral indices may help to constrain the origin of the radio emission in the faint radio sources and may actually be fundamental for understanding eventual links to the optical light. This is especially true if high resolution radio data are available and source structures can be inferred.

Multi-frequency radio data are available only for a few very small ($\lesssim 60$ sources) sub-mJy samples. Such studies indicate that most mJy radio sources are of the steep-spectrum type ($\alpha < -0.5$, assuming $S \sim \nu^\alpha$), with evidence for flattening of the spectra at lower flux densities (Donnelly et al. 1987; Gruppioni et al. 1997; Ciliegi et al. 2003). This flattening is consistent with the presence of many flat ($\alpha > -0.5$) and/or inverted ($\alpha > 0$) spectral index sources at μJy flux densities (Fomalont et al. 1991; Windhorst et al. 1993). On the other hand, there is still disagreement about the interpretation of such results.

In the μJy population studied by Windhorst et al. (1993) 50% of the sources have intrinsic angular size $\Theta \geq 2.6 \pm 1.4$ arcsec, corresponding to $\simeq 5 - 40$ kpc at the expected median redshift of the sources. Extended (kpc-scale) steep-spectrum radio sources suggest synchrotron emission in galactic disks, while extended flat-spectrum sources may indicate thermal bremsstrahlung from large scale star-formation both occasionally with opaque radio cores. On the other hand, Donnelly et al. (1987) claim that most of the sub-mJy blue radio galaxies have steep radio spectra and are physically quite compact (≤ 4 kpc). This suggests two possible alternative mechanisms for the radio emission: 1) a nuclear starburst occurring on a few kpc scale in the galaxy center; 2) a non-thermal nucleus on parsec scales. Only high resolution radio observations could decide between them.

With the aim of studying the spectral index behaviour of the faint radio population, we imaged at 5 GHz a one square degree area of the ATESP 1.4 GHz survey ($S_{\text{lim}} \sim 0.5$ mJy, Prandoni et al. 2000a,b), for which deep ($R < 25.5$) optical multi-color data is available, as part of an ESO public survey (e.g. Mignano et al. 2006). Such deep optical imaging will provide optical identification and photometric redshifts for most of the radio sources.

We notice that the ATESP is best suited to study the sources populating the flux interval $0.5 - 1$ mJy, where starburst galaxies start to enter the counts, but are not yet the dominant population. This means that our sample can be especially useful to study the issue of low-luminosity nuclear activity, possibly related to low efficiency accretion processes and/or radio-intermediate/quiet QSOs.

The present 5 GHz observations are valuable because i) the higher resolution images probe the radio source structure at small scales (≤ 2 arcsec) and thus we can hopefully distinguish between disk-scale and nuclear-scale radio emission, and ii) the present 5 GHz survey is the largest at sub-mJy fluxes, by a factor $10 - 100$: previous samples typically cover from < 0.01

to ~ 0.1 square degrees (e.g. Bennett et al. 1983; Fomalont et al. 1984, 1991; Donnelly et al. 1987; Partridge et al. 1986; Ciliegi et al. 2003).

In this paper we describe the ATESP 5 GHz survey, present the 5 GHz source catalogue and counts, and discuss the spectral index properties of the ATESP radio sources. The analysis of the optical properties of the sample will be the subject of a following paper (Mignano et al. in preparation).

The paper is organized as follows. In Sect. 2 we briefly present the 1.4 GHz ATESP survey and the multi-color optical data coming from the ESO Deep Public Survey (DPS). Sect. 3 describes the ATESP 5 GHz survey observations and data reduction. The radio mosaics we produced are discussed in Sect. 4, while Sect. 5 describes the source extraction and parameterization procedure. The 5 GHz source catalogue is presented in Sect. 6, together with an analysis of the source size and structure. The 5 GHz source counts derived from the present survey and the $1.4 - 5$ GHz spectral index properties of the ATESP sources are presented in Sect. 7. A summary is given in Sect. 8.

2. The 1.4 GHz ATESP Survey and Related Optical Information

The ATESP 1.4 GHz survey (Prandoni et al. 2000a) was carried out with the Australia Telescope Compact Array (ATCA); it consists of 16 mosaics with $8'' \times 14''$ resolution and uniform sensitivity (1σ noise level $\sim 79 \mu\text{Jy}$), covering two narrow strips of $21^\circ \times 1^\circ$ and $5^\circ \times 1^\circ$ near the SGP, at decl. -40° . The ATESP 1.4 GHz survey has produced a catalogue of 2967 radio sources, down to a flux limit (6σ) of $S \sim 0.5$ mJy (Prandoni et al. 2000b).

In order to alleviate the identification work, the area covered by the ATESP survey was chosen to overlap with the region where Vettolani et al. (1997) made the ESP (*ESO Slice Project*) redshift survey. They performed a photometric and spectroscopic study of all galaxies down to $b_J \sim 19.4$. The ESP survey yielded 3342 redshifts (Vettolani et al. 1998), to a typical depth of $z = 0.1$ and a completeness level of 90%.

In the same region lies the *ESO Imaging Survey* (EIS) Patch A ($\sim 3^\circ \times 1^\circ$ square degrees, centered at $22^h40^m, -40^\circ$), mainly consisting of images in the I-band out of which a galaxy catalogue 95% complete to $I = 22.5$ has been extracted (Nonino et al. 1999). This catalogue allowed us to identify $\sim 57\%$ of the 386 ATESP sources present in that region. A first radio/optical analysis of a magnitude-limited sub-sample of 70 sources was presented by Prandoni et al. (2001b).

More recently, a different strip of $2^\circ \times 0.5^\circ$ within the ATESP region at $22^h50^m40^s, -40^\circ13'$ was selected for a very deep multi-color ESO public survey: the Deep Public Survey (DPS), which was carried out with the Wide Field Imager (WFI) at the 2.2 m ESO telescope. This one square degree region is covered by 4 WFI fields (referred to as DEEP1a,b,c and d). In this region *UBVRI* imaging down to very faint magnitudes is available (see Mignano et al. 2006): $U \sim 25$, $B \sim 25.8$, $V \sim 25.2$, $R \sim 25.5$, $I \sim 24$ (5σ , 2 arcsec aperture magnitudes). In addition, DEEP1a and b have been observed in the infrared with SOFI at NTT down to $K_{AB} \sim 21.3$, while deeper J- and

K-band images ($J_{AB} < 23.4$ and $K_{AB} < 22.7$) have been taken for selected sub-regions (see Olsen et al., 2006)

A sketch of the sky coverage of the surveys described in this section is given in Fig. 1.

3. The Observations

3.1. Observing Strategy

We imaged the entire DEEP1 2×0.5 degree region at 5 GHz, since it has the best optical coverage. The area was spanned with a radio mosaic consisting of 21×6 pointings (fields) at $6'$ spacing, i.e. $\text{FWHM}/\sqrt{2}$, where $\text{FWHM} = 10'$ is the full width at half maximum of the primary beam (see Prandoni et al. 2000a). If we aim at virtually detecting all the 1.4 GHz ATESP sources with radio spectral index $\alpha \geq -0.7$, we need to reach a 5 GHz point source detection limit of $3\sigma \approx 0.2$ mJy.

Of course, correct spectral index determination can only be made if the 5 and 1.4 GHz beams have the same size, as severe incompleteness would result if the extra resolution at 5 GHz were used. Therefore we produced 5 GHz radio mosaics with the same spatial resolution as for the ATESP 1.4 GHz mosaics. We thus used the Compact Array in the 1.5 km configuration. On the other hand we also requested the 6 km antenna. While we want to extract the source catalogue from the low resolution mosaic, the longer baselines to the 6km antenna were exploited to get additional information on the radio source structure (see Sect. 6.2).

Each field (with 2×128 MHz bandwidth and 10 baselines) was observed for 98 minutes, which results in a final uniform noise level of $\sim 64 \mu\text{Jy}$. Therefore all $21 \times 6 = 126$ fields could be observed in 18 blocks of 12 hours (allowing also for calibration time). Care was taken to obtain good hour angle coverage, by cycling continually through the individual field during the observing process. Since we wanted to observe the entire region also with the 6 km configuration, an additional 12 hours were used for that purpose.

The observing log is given in Table 1. Note that the use of different 1.5 km arrays is not relevant for the present study. The two 128 MHz bands were set at 4800 and 5056 MHz.

The flux density calibration was performed through observations of the source PKS B1934-638, which is the stan-

Table 1. Log of the observations.

Date	t_{obs} h	Array
13/10/00	1×12	6A
16/11/00–19/11/00	3×12	1.5B

02/08/01–10/08/01	5×12	1.5A
29/10/01–03/11/01	4×12	1.5D

dard primary calibrator for ATCA observations ($S = 5.8$ Jy at $\nu = 4800$ MHz as revised by Reynolds 1994, Baars et al. 1977 flux scale). The phase and gain calibration was based on observations of a secondary calibrator (source 2254-367) selected from the ATCA calibrator list.

3.2. Data Reduction

For the data reduction we used the *Australia Telescope National Facility* (ATNF) release of the *Multichannel Image Reconstruction, Image Analysis and Display* (MIRIAD) software package (Sault et al. 1995).

Every single 12^{h} run and each of the two observing bands were flagged and calibrated following standard procedures for ATCA observations, as described in Prandoni et al. (2000a).

Sensitivity and $u-v$ coverage were improved for each field by merging, before imaging and cleaning, the visibilities coming from all the observing runs and from the two observing bands. Imaging and deconvolution was done simultaneously for several pointings. This is not only simpler and faster, but also produces better results, as overlapping pointings can make use of a higher number of visibilities and side lobes of sources in contiguous fields can be easily cleaned.

We produced mosaics at both *low* and *full* resolution ($\sim 10''$ and $\sim 2''$ respectively). Two low resolution mosaics covered the entire $2^\circ \times 0.5^\circ$ region, while in full resolution 30 overlapping mosaics of 9 pointings each were produced. Final images were obtained by cleaning after (phase only) self calibration.

Table 2. Main parameters for the 2 low resolution mosaics and average values from the 30 full resolution mosaics.

Snapshot surveys like the present one are typically affected by the *clean bias* effect: the deconvolution process can produce a systematic underestimation of the source fluxes, as consequence of the loose constraints to the cleaning algorithm due to sparse $u-v$ coverage (see White et al. 1997; Condon et al. 1998). The clean bias effect has been discussed in great detail (Prandoni et al. 2000a), and we repeat here only that such a systematic effect can be kept under control if cleaning is stopped well before the maximum residual flux has reached the theoretical noise level. Specifically, we set the cleaning limit at 4 times the theoretical noise, since simulations made by us show that this cut-off ensures that the clean bias does not affect source fluxes.

Another systematic effect that has to be taken into account is bandwidth smearing. It is well known that at large distance from the pointing centre bandwidth smearing tends to reduce the peak flux and increase the apparent source size in the radial direction, such that total flux remains conserved. Also this effect has been discussed by us extensively in an earlier paper on the ATESP 1.4 GHz survey (Prandoni et al. 2000b), in particular in the context of radio mosaics. Considering that the pass-band width is 4 MHz, for the multichannel 32 $\times$ 4 MHz continuum mode observations, and the observing frequency about 5000 MHz, it is easily seen from equation (8) in Prandoni et al. (2000b) that the ratio between smeared and unsmeared peak flux is between 0.9999 and 1. Consequently bandwidth smearing is of no concern for our 5 GHz survey.

4. The Radio Mosaics

4.1. Production of the Mosaics

As mentioned before, we needed to produce mosaics at exactly the same resolution as the 1.4 GHz images (see Prandoni et al. 2000a), in order to be able to compare the data at two frequencies and determine reliable spectral indices. We therefore used only the 10 baselines shorter than 3 km. Radio maps with 520 $\times$ 520 pixels of 2.5 arcsec were made, and combined into two mosaics. In this way all the flux in the primary beam (which is 20.6 arcmin at 4800 MHz) is recovered. Details on

the two low resolution mosaics (which are of the order of 2000 $\times$ 1200 pixels, and have a small overlap) are given in Table 2: we list the number of fields composing the mosaics (columns $\times$ rows), the tangent point (sky position used for geometry calculations) and the restoring synthesized beam (size in arcsec and position angle).

Since the aim of the low resolution imaging is basically sensitivity, natural weighting was used in the deconvolution process. However, this choice may introduce some spatially correlated features and this may affect the zero level of faint radio sources. This problem can be avoided by removing all baselines shorter than 60 m from the data prior to imaging and deconvolving.

Although this means that $\sim 3-7\%$ of the visibilities in 1.5B and 1.5F configurations had to be rejected, this had hardly any adverse effect on the quality of the mosaics. The lack of the shortest spacings would in principle lead to an increased insensitivity to sources larger than 90", but in reality less than one source with angular size $> 90''$ is expected in the area and flux range covered by the present survey (as discussed in Sect. 6.2). Therefore the effect on completeness and flux densities should be minimal.

In order to assess the radio source structures full resolution images were produced. The 2 $\times$ 0.5 sq. degr. region was covered by a grid of 30 overlapping mosaics, each composed by 3 $\times$ 3 or 3 $\times$ 2 fields. A size of 2060 $\times$ 2060 pixels (with a pixel size of 0.6") for each field in the mosaics ensured complete recovery of the whole flux in the field of the primary beam. Some average parameters of the full resolution mosaics are given in Table 2.

4.2. Noise Analysis of the Mosaics

The 5 GHz survey was designed to give uniform noise in the central 1.0° $\times$ 0.5° regions of the two low resolution mosaics, which together cover the area of the DEEP1 optical survey (see Mignano et al. 2006). In the following our noise analysis always refers to this region. In column 7 of Table 2 we list the minimum (negative) flux $S_{\min}$ found in the image, in column 8

Fig. 2. *Top:* Grey scale of the noise maps obtained from the two low resolution mosaics: fld1to11 (*Top*) and fld10to21 (*Bottom*). Darker regions correspond to higher noise. The rectangular boxes indicate the region corresponding to the DEEP1 area, where the survey was designed to provide a uniform noise level. The contour images represent the theoretical sensitivity computed by taking into account the observing time actually spent on the mosaiced single fields: contours refer to 1.1, 1.0, 0.9, $0.8 \times$ the mean noise value estimated in the noise maps (see Fig. 3). As expected the actual noise variations trace reasonably well the theoretical ones.

the noise σ_{fit} estimated as the FWHM of the flux distribution in the pixels in the range $\pm S_{\text{min}}$, and in column 9 the noise $\langle \sigma \rangle$ estimated as the standard deviation of the average flux in several source-free sub-regions of the mosaics. σ_{fit} was used to check the presence of correlated noise, while $\langle \sigma \rangle$ gives an idea of the uniformity of the noise over the area of the mosaic. As expected, noise variations in general do not exceed $\sim 10\%$,

with the sole exception of one of the full resolution mosaics, due to the presence of an $S = 27$ mJy source that could not effectively be self-calibrated. On average we find a noise level around $\sim 70 \mu\text{Jy}$; therefore a 3σ detection limit for a 5 GHz source at the position of a 1.4 GHz source is ~ 0.21 mJy. In all mosaics the noise is essentially Gaussian.

A more detailed analysis of the noise has been performed for the two low resolution mosaics, since they are used for source extraction. The root-mean-square variations of the background were determined with the software package SExtractor¹ (Bertin & Arnouts 1996), which was developed for the analysis of optical images, but is known to work well also on radio images (see Bondi et al. 2003, Huynh et al. 2005).

In computing the local background variations we used a mesh size of 32×32 pixels (or equivalently 8×8 beams) as this was empirically found to be a good compromise: too small mesh sizes would suffer from individual source statistics, while large meshes would miss large, real systematic variations of the background. We remark that a very similar mesh size proved to work well for the ATCA 1.4 GHz survey of the HDF South done by Huynh et al. (2005).

The noise maps for the two low resolution mosaics are shown in Fig. 2 (grey scale). Also shown are the expected theoretical sensitivities due field to field variations in the actual observing time (contours). We notice that the measured noise is quite uniform in the inner part of the mosaics, and traces the expected sensitivity quite well.

In Fig. 3 we plot the pixel flux value distributions in the noise maps. The vertical dotted lines indicate the mean value of the distributions ($68.5 \pm 4.4 \mu\text{Jy}$ for fld1to11 and $63.3 \pm 4.2 \mu\text{Jy}$ for fld10to21) and the corresponding $\pm 10\%$ variations. We notice that such noise values are in very good agreement with the average noise values obtained directly from the radio mosaics (see Tab. 2). In addition the two distributions in Fig. 3 clearly show that noise variations larger than 10% are very rare. In particular the largest noise values are found in presence of strong radio sources, while the lowest noise values are due to longer observing times on some fields.

The noise maps derived for the two low resolution mosaics have been used to define a local signal to noise ratio, i.e. a local threshold, for the source detection (see Sect. 5).

5. Source Extraction

As for our 1.4 GHz survey we used the algorithm IMSAD (*Image Search and Destroy*), available as part of the MIRIAD package for the source extraction and parameterization. The source catalogue thus obtained is based on the low resolution mosaics exclusively.

As a first step, we extracted all sources with peak flux $S_{\text{peak}} \geq 4.5\sigma$, where $\sigma = \sigma_{\text{fit}}$ is the average mosaic rms flux density (see Table 2). This yielded a preliminary list of 141 source components with $S_{\text{peak}} \gtrsim 0.3 \text{ mJy}$ in a total area of $2 \times 0.5 \text{ sq. degr.}$

All the sources were then visually inspected in order to check for obvious failures and/or possibly poor parameterization. Whenever necessary the sources were re-fitted. The checking/re-fitting procedures adopted in this work are the same as used for the compilation of the 1.4 GHz ATESP source catalogue and we refer to Sect. 2 of Prandoni et al. (2000b) for a full description. In a few cases Gaussian fits were able to provide good values for positions and peak flux densities, but

Fig. 3. Pixel flux value distribution in the (inner part of) noise maps. *Top:* fld1to11. *Bottom:* fld10to21. The vertical dotted lines indicate the mean value and the corresponding $\pm 10\%$ variations for each map.

did fail in determining the integrated flux densities. This happens typically at faint fluxes ($< 10\sigma$). Gaussian sources with a poor determination of S_{total} are flagged in the catalogue (see Sect. 6.1).

After obtaining reliable parameters for all the sources, we used the noise maps described in Sect. 4.2 to compute the local signal-to-noise ratio for each source. Any source with $S_{\text{peak}} \geq 6\sigma_{\text{local}}$ was then included in the final list: 115 sources (or source components) satisfy this criterion. The peak flux density distribution for the final source sample is shown in Fig. 4.

Fig. 5 shows the so-called *visibility area* of the ATESP 5 GHz survey, i.e. the fraction of the total area covered by the survey, over which a source with given S_{peak} satisfies the $S_{\text{peak}} \geq 6\sigma_{\text{local}}$ criterion. We notice that the visibility area increases quite rapidly with flux and becomes equal to 1 at $S_{\text{peak}} \sim 0.5 \text{ mJy}$.

5.1. Multiple and Non-Gaussian Sources

When we search for possible multiple-component sources, we find that the nearest neighbour pair separations are always $d \gtrsim 40''$, with the exception of four cases, where pair separations are $13.1''$, $18.3''$, $18.4''$ and $20.0''$ respectively. We decided to catalogue these 4 pairs with $d \lesssim 20''$ as double sources. We notice that three of them show clear signs of association and are the result of the splitting performed by the source fitting procedure itself. Moreover, they are listed as double sources also in the ATESP 1.4 GHz catalogue (Prandoni et al. 2000b). The fourth pair case ($d = 20.0''$) is less obvious,

¹ We used SExtractor Version 2.2.2

Fig. 4. Peak flux density distribution of the 115 5 GHz radio sources (or source components) with $S_{\text{peak}} \geq 6\sigma_{\text{local}}$.

Fig. 5. Visibility area of the ATEP 5 GHz survey. Fraction of the total area over which a source with given measured peak flux density can be detected.

since no clear signs of association are visible. Nevertheless this object is listed as triple source in the ATEP 1.4 catalogue. The final 5 GHz source list consists then in 111 distinct objects: 107 single sources and 4 double sources.

The position of multiple sources is defined as the radio centroid, i.e. as the flux-weighted average position of all the components. Integrated global source flux densities are computed

by summing all the component integrated fluxes. The global source angular size is defined as *largest angular size (las)* and it is computed as the maximum distance between the source components.

We have also four sources which could not be parametrised by a single or multiple Gaussian fit. *Non-Gaussian* sources have been parameterized as follows: positions and peak flux densities have been derived by a second-degree interpolation of the flux density distribution. This means that positions refer to peak positions, which, for non-Gaussian sources does not necessarily correspond to the position of the core. Integrated fluxes have been derived directly by summing pixel per pixel the flux density in the source area, defined as the region enclosed by the $\geq 3\sigma$ flux density contour. The source position angle was determined by the direction in which the source is most extended and the source axes were defined again as *las*, i.e., in this case, the maximum distance between two opposite points belonging to the 3σ flux density contour along (major axis) and perpendicular to (minor axis) the same direction. These four non-Gaussian sources were catalogued at 1.4 GHz as follows: 2 non-Gaussian sources, 1 double source, 1 single Gaussian source.

5.2. Deconvolution

The ratio of the integrated flux to the peak flux is a direct measure of the extension of a radio source:

$$S_{\text{total}}/S_{\text{peak}} = \theta_{\text{min}} \theta_{\text{maj}} / b_{\text{min}} b_{\text{maj}} \quad (1)$$

where θ_{min} and θ_{maj} are the source FWHM axes and b_{min} and b_{maj} are the synthesized beam FWHM axes. The flux ratio can therefore be used to discriminate between extended (larger than the beam) and point-like sources.

In Fig. 6 we show the flux ratio as a function of signal-to-noise for the 115 sources (or source components) detected above the $6\sigma_{\text{local}}$ -threshold. Values for $S_{\text{total}}/S_{\text{peak}} < 1$ are due to the influence of the image noise on the measure of source sizes and therefore of the source integrated fluxes. Following Prandoni et al. (2000b, Sect. 3.1), we have taken into account such errors by considering as unresolved all sources which lie below the curve defined by:

$$S_{\text{total}}/S_{\text{peak}} < 1 + \left[\frac{a}{(S_{\text{peak}}/\sigma_{\text{local}})^\beta} \right] \quad (2)$$

where $a = 10$ and $\beta = 1.5$ (upper dashed line in Fig. 6). Such curve is obtained by determining the lower envelope of the flux ratio distribution (the curve containing 90% of the $S_{\text{total}} < S_{\text{peak}}$ sources, see lower dashed line in Fig. 6) and then mirroring it on the $S_{\text{total}} > S_{\text{peak}}$ side.

From this analysis we found that $\sim 70\%$ of the sources (or source components) have to be considered unresolved (dots in Fig. 6). Deconvolved angular sizes are considered meaningful and given in the catalogue only for extended sources (filled circles in Fig. 6); for unresolved sources, angular sizes are set to zero in the catalogue (see Table 6).

Fig. 6. Ratio of the integrated flux S_{total} to the peak one S_{peak} as a function of the source signal-to-noise. The horizontal dotted line indicates the $S_{\text{total}} = S_{\text{peak}}$ locus. Also shown (dashed lines) are the lower and upper envelopes (ref. Eq. 2) of the flux ratio distribution containing $\sim 90\%$ of the unresolved sources (dots). Filled circles indicate extended sources.

5.3. Source Parameters at full resolution

The sources extracted from the low resolution mosaics and catalogued in Table 6 were then searched for in the full resolution mosaics, in order to get additional information on their radio morphology. The detection threshold was set to $3\times$ the local noise level, as allowed whenever the source position is known a priori. The local noise was evaluated in a $\sim 1' \times 1'$ box centered on the source position. Above $3\sigma_{\text{local}}$ we detected 109 of the 111 sources catalogued at low resolution.

The source full-resolution parameterization has been performed using similar procedures as used at low resolution. Whenever the source peak flux densities were $\geq 6\sigma_{\text{local}}$ we performed a two-dimensional Gaussian fit. The sources were then visually inspected and re-fitted, whenever necessary. We also applied Eq. 2 (with $a = 5$, $\beta = 1.5$) to separate point sources from extended ones.

The full-resolution parameters for each source are reported in Table 6 (Columns 11-20). For sources detected at $< 6\sigma_{\text{local}}$ (flagged 'D' in the catalogue) we provide only position and peak flux density. In two cases, where the source is very extended and the structure is well recognized, we list all the parameters. Such cases are flagged 'DE'. For the two undetected sources (flagged 'U' in the catalogue) we provide peak flux upper limits only.

We notice that 28 sources that are point-like at low resolution get deconvolved at full resolution, implying physical sizes of $1 - 3$ arcsec. In 3 additional cases, sources which appear as single at low resolution are split in two components at full reso-

lution. Contour images of these three sources, together with the four sources catalogued as double at low resolution, are shown in Fig. 7.

5.4. Errors in the Source Parameters

Parameter uncertainties are the quadratic sum of two independent terms: the calibration errors, which usually dominate at high signal-to-noise ratios, and the internal errors, due to the presence of noise in the maps, which dominate at low signal-to-noise ratios.

For an estimation of the internal errors in the 5 GHz source parameters we refer to Condon's master equations (Condon 1997), which provide error estimates for elliptical Gaussian fitting procedures. Such equations already proved to be adequate to describe the measured internal errors for the ATESP 1.4 GHz source parameters (Prandoni et al. 2000b), which have been obtained in a very similar way: same detection algorithm (IMSA) applied to very similar radio mosaics.

Flux calibration errors are in general estimated from comparison with consistent external data of better accuracy than the one tested. Due to the lack of data of this kind in the region covered by the ATESP 5 GHz survey, we assume the same calibration errors as for the ATESP 1.4 GHz survey, e.g. $5 - 10\%$ for both flux densities and source sizes (see Appendix A in Prandoni et al. 2000b).

6. The ATESP 5 GHz Sources

6.1. The 5 GHz Source Catalogue

The 5 GHz source catalogue is reported in Table 6. The catalogue is sorted on right ascension. Each source is identified by an IAU name (Column 1) and is defined by its low resolution parameters (Columns 2 – 10).

The corresponding full resolution parameters are reported in Columns 11 – 19. The detailed format is the following:

Column (1) - Source IAU name. For multiple sources we list all the components (labeled 'A', 'B', etc.) preceded by a line (flagged 'M', see Column 9) giving the position of the radio centroid, the source global flux density and its overall angular size.

Column (2) and (3) - Source position: Right Ascension and Declination (J2000).

Column (4) and (5) - Source peak (S_{peak}) and integrated (S_{total}) flux densities in mJy (Baars et al. 1977 scale).

Column (6) and (7) - Intrinsic (deconvolved from the beam) source angular size. Full width half maximum of the major (Θ_{maj}) and minor (Θ_{min}) axes in arcsec. Zero values refer to unresolved sources (see Sect. 5.2).

Column (8) - Source position angle (P.A., measured N through E) for the major axis in degrees.

Column (9) - Flag indicating the fitting procedure and parameterization adopted for the source (or source component). 'S' refers to Gaussian fits; 'S*' refers to poor Gaussian fits (see Sect. 5); 'E' refers to non-Gaussian sources and 'M' refers to multiple sources (see Sect. 5.1).

Fig. 7. $1' \times 1'$ contour images of multiple sources in the catalogue: 7 sources split in two or more components at either low or full resolution. Gray lines are for low resolution contours and black lines are for full resolution contours. For each source the contour levels are at 3, 4.5, 6, 10, 20, 50, $100 \times$ the local noise level. Synthesized beams at low and full resolution are shown in the lower left corner.

Column (10) - Local noise level used for the source detection in μJy (see Sects. 4.2 and 5).

Columns (11) to (17) - Same as Columns (2) to (8), but referring to full resolution source parameterization.

Column (18) - Same as Column (9), but referring to full resolution source parameterization. Here additional flags are defined for any sources with peak flux $3\sigma_{\text{local}} \leq S_{\text{peak}} < 6\sigma_{\text{local}}$ and undetected sources (see Sect. 5.3). In a few cases references are given to additional notes on full resolution source radio morphology (reported as footnotes at the end of the table).

Column (19) - Same as Column (10) but referring to full resolution mosaics (see Sect. 5.3).

6.2. Source Structure and Size

A comparison between full and low resolution source parameters gives interesting information about the source size and structure.

In Fig. 8 we compare the flux densities at low and full resolution for the 104 ATESP 5 GHz sources, catalogued as single sources (we exclude the 7 multi-component sources shown in Fig. 7). We find a good correlation between the low and full resolution fluxes, although a number of sources show a systematic integrated flux underestimation at the higher spatial resolution. Such a resolution effect is due to the loss of low surface brightness flux in extended sources, as it is evident from the compari-

Fig. 8. Low resolution vs. full resolution flux densities for the ATEP 5 GHz sample (multiple-component sources are not plotted). We define the flux as S_{total} whenever a source is resolved and as S_{peak} otherwise. Dashed lines represent the $S_{\text{full res.}} = S_{\text{low res.}}$ line and the 1σ confidence limits in the flux measurements. The horizontal dotted line indicates the average 6σ detection limit at full resolution. Blue dots: sources appearing point-like at both low and full resolution; green empty squares: sources that are point-like at low resolution, but resolved at full resolution; magenta pentagons: sources point-like at low resolution and detected at $< 6\sigma_{\text{local}}$ at full resolution (flagged 'D' in Column 18 of Table 6); cyan filled triangles (pointing downwards): sources that are point-like at low resolution but undetected at full resolution (flagged 'U' in Column 18 of Table 6); red empty triangles: sources resolved at both low and full resolution; red filled triangles: sources resolved at low resolution and point-like at full resolution; bold magenta pentagons: sources resolved at low resolution and detected at $< 6\sigma_{\text{local}}$ at full resolution (flagged 'D' or 'DE' in Column 18 of Table 6).

son between Fig. 8 and Fig. 9, where we plot the source deconvolved angular sizes as a function of flux density. In fact the largest sources are typically the ones with largest flux underestimations at full resolution. The most extreme cases regard sources which are resolved at low resolution and are catalogued as point-like (red filled triangles) or even as $< 6\sigma_{\text{local}}$ detections (bold magenta pentagons) at full resolution. In such cases the extended flux gets almost entirely resolved out. We illustrate this effect in Fig. 13, where we show contour images of the 12 most extended single-component sources ($\Theta_{\text{maj}} > 8''$). Among such sources there are several cases of low surface brightness sources, which are barely detected at full resolution, and a few cases where full resolution reveals elongated structures and/or hints of multiple components.

Fig. 9. Deconvolved angular size ($\Theta = \Theta_{\text{maj}}$) as a function of integrated flux density (same sources and symbols as in Fig. 8). We plot low resolution source parameters, except when the source is unresolved at low resolution: in that case we use the full resolution Θ_{maj} estimation. For sources unresolved at both low and full resolution we set $\Theta = 0$ and use the peak flux density. The dot-dashed line represents the size (Θ_{max}) above which the ATEP 5 GHz sample gets uncomplete, due to the resolution bias. The two solid lines indicate the minimum angular size (Θ_{min}), below which deconvolution is not considered meaningful at low (red upper line) and at full (blue lower line) resolution respectively. Dashed lines indicate the median source sizes as a function of flux as expected from the Windhorst et al. (1990) relation. Such lines have to be compared to the broken solid line which represents the median source sizes for different flux intervals, as measured in our sample. The inner panel shows the angular size distribution ($h(>\Theta)$) proposed by Windhorst et al. (dashed lines), compared to the size distribution of sources in our sample (broken solid line). See text for more details.

The two solid lines in Fig. 9 indicate the minimum angular size, Θ_{min} , below which deconvolution is not considered meaningful at either low (red upper line) or full resolution (blue lower line). They are derived from Eqs. (1) and (2), by setting the appropriate b_{min} , b_{maj} , a and β parameters. We notice that full resolution allows us to get size information for sources with intrinsic sizes ranging from 1 – 2 arcsec to ~ 4 arcsec (green empty squares). This means that we can successfully deconvolve $\sim 80\%$ of the ATEP 5 GHz sources with $S_{\text{low res}} > 0.7$ mJy and $\sim 90\%$ of the sources with $S_{\text{low res}} > 1$ mJy. Above such flux limits, where we have a limited number of upper limits, we can reliably undertake a statistical analysis of the size properties of our sample. In Fig. 9 we compare the median angular size measured in different flux intervals for the ATEP 5 GHz sources with $S > 0.7$ mJy (broken solid line) and the

angular size integral distribution derived for the ATEP 5 GHz sources with $1 < S(\text{mJy}) < 5$ (broken solid line in the inner panel) to the ones obtained from the Windhorst et al. (1990) relations proposed for 1.4 GHz samples: $\Theta_{\text{med}} = 2'' \cdot S_{1.4\text{GHz}}^{0.30}$ (S in mJy) and $h(> \Theta) = e^{-\ln 2 (\Theta/\Theta_{\text{med}})^{0.62}}$. Θ_{med} and $h(> \Theta)$ are extrapolated to 5 GHz using three different values for the spectral index: $\alpha = 0, -0.5$ and -0.7 (see black dashed lines). We notice that in the flux ranges considered our determinations show a very good agreement with the ones of Windhorst et al. (1990).

On the other hand, we are not able to say much about the faintest sources ($S < 0.7$ mJy), which remain largely unresolved even at full resolution, and constitute about 40% of our sample. We can only argue that the angular sizes of such sources are smaller than $1 - 2$ arcsec. Such upper limits are consistent with the size analysis performed by Fomalont et al. (1991) for a deeper sample selected at the same frequency (5 GHz): 16/19 (84%) sources with $0.06 < S(\text{mJy}) < 0.8$ have $\Theta < 1.5$ arcsec. On the other hand, the median values derived from the Windhorst et al. relation (transformed to 5 GHz) might be possibly overestimating the real values (compare black dashed lines to full resolution blue solid line in Fig. 9).

We finally notice that flux losses in extended sources not only affect the full resolution parameterization of the ATEP 5 GHz sources (as shown in Fig. 8), but can also cause incompleteness in the ATEP 5 GHz catalogue itself (defined at low resolution). A resolved source of given S_{total} will drop below the peak flux density detection threshold more easily than a point source of same S_{total} . This is the so-called *resolution bias*.

Eq. (1) – with the low resolution parameter setting – can be used to give an approximate estimate of the maximum size (Θ_{max}) a source of given S_{total} can have before dropping below the $S_{\text{peak}} = 6\sigma_{\text{local}}$ limit of the ATEP 5 GHz catalogue. Such limit is represented by the black dot-dashed line plotted in Fig. 9. As expected, the angular sizes of the largest ATEP 5 GHz sources approximately follow the estimated $\Theta_{\text{max}} - S$ relation.

In principle there is a second incompleteness effect, related to the maximum scale at which the ATEP 5 GHz low resolution mosaics are sensitive due to the lack of baselines shorter than 60 m. According to it, we expect the ATEP 5 GHz sample to become progressively insensitive to sources larger than $90''$ (see Sect. 4.1). This latter effect can, however, be neglected in this case, because it is smaller than the previous one over the entire flux range spanned by the ATEP 5 GHz survey. Moreover, if we assume the angular size distribution proposed by Windhorst et al. (1990), we expect < 1 sources with $\Theta > 90''$ in the area and flux range covered by our survey.

7. Results

7.1. The ATEP 5 GHz Source Counts

We used the 111 5 GHz ATEP sources to derive the differential source counts as a function of flux density. In computing the counts we have used the catalogue as defined at low resolution to minimize incompleteness induced by resolution effects. Integrated flux densities were used for extended sources and peak flux densities for point-like sources.

Table 3. ATEP 5 GHz source counts.

ΔS (mJy)	$< S >$ (mJy)	N_S	dN/dS $\text{sr}^{-1} \text{Jy}^{-1}$	N/N_{exp}
0.37 – 0.52	0.44	22	6.92×10^8	$0.031^{+0.008}_{-0.007}$
0.52 – 0.74	0.62	24	4.67×10^8	$0.050^{+0.010}_{-0.010}$
0.74 – 1.05	0.88	17	2.20×10^8	$0.056^{+0.017}_{-0.014}$
1.05 – 1.48	1.24	12	1.05×10^8	$0.064^{+0.024}_{-0.018}$
1.48 – 2.09	1.76	12	7.24×10^7	$0.104^{+0.040}_{-0.030}$
2.09 – 4.19	2.96	12	2.06×10^7	$0.106^{+0.040}_{-0.031}$
4.19 – 8.37	5.92	8	6.74×10^6	$0.197^{+0.094}_{-0.070}$
8.37 – 16.7	11.8	2	8.26×10^5	$0.137^{+0.180}_{-0.088}$
16.7 – 33.5	23.7	2	4.06×10^5	$0.380^{+0.502}_{-0.245}$

Each source has been weighted for the reciprocal of its visibility area ($\Omega(S_{\text{peak}})/\Omega_{\text{tot}}$, see Fig. 5), that is the fraction of the total area over which the source could be detected. We notice that for $S_{\text{peak}} > 0.5$ mJy a source can be counted over the whole survey area. Moreover, we have taken properly into account the catalogue incompleteness in terms of integrated flux density, due to the resolution bias discussed in the previous section. The correction c for the resolution bias has been defined following Prandoni et al. (2001a) as:

$$c = \frac{1}{1 - h(> \Theta_{\text{lim}})} \quad (3)$$

where $h(> \Theta_{\text{lim}})$ is the integral angular size distribution proposed by Windhorst et al. (1990) for 1.4 GHz samples, which turned out to be a good representation of the ATEP 5 GHz source sizes at least down to $S \sim 0.7$ mJy (see Sect. 6.2). Here we transform the Windhorst et al. relation to 5 GHz using $\alpha = -0.5$, chosen as reference value (see also Sect. 7.2).

Θ_{lim} represents the angular size upper limit, above which we expect to be incomplete. This is defined as a function of the integrated source flux density as (see Prandoni et al. 2001a):

$$\Theta_{\text{lim}} = \max[\Theta_{\text{min}}, \Theta_{\text{max}}] \quad (4)$$

where Θ_{min} and Θ_{max} are the parameters defined in Sect. 6.2. The $\Theta_{\text{min}} - S$ relation (red upper solid line in Fig. 9) is important at low flux levels where Θ_{max} (black dot-dashed line in Fig. 9) becomes unphysical (i.e. $\rightarrow 0$). In other words, introducing Θ_{min} in the equation takes into account the effect of having a finite synthesized beam size (that is $\Theta_{\text{lim}} \gg 0$ at the survey limit) and a deconvolution efficiency which varies with the source peak flux.

The 5 GHz ATEP source counts are shown in Fig. 10 (filled circles) and listed in Table 3, where, for each flux interval (ΔS), the geometric mean of the flux density ($< S >$), the number of sources detected (N_S), the differential source density (dN/dS) and the normalized differential counts (N/N_{exp}) are given. Also listed are the Poissonian errors (calculated following Regener 1951) associated to the normalized counts. For

Fig. 10. Normalized 5 GHz differential source counts for different samples: Ciliegi et al. 2003 (empty pentagons), Fomalont et al. 1991 (filled triangles), Wrobel & Krause 1990 (filled squares), Donnelly et al. 1987 (empty triangles), Partridge et al. 1986 (stars), Altshuler 1986 (asterisks), Bennett et al. 1983 (empty squares). The ATEP 5 GHz source counts presented here (filled circles plus single empty circle) are corrected for resolution bias as explained in the text. Vertical bars represent Poissonian errors on the normalized counts.

comparison with other 5 GHz studies, the source counts are normalized to a non evolving Euclidean model which fits the brightest sources in the sky. We notice that at 5 GHz the standard Euclidean integral counts are $N(> S) = 60 \times S^{-1.5} \text{ sr}^{-1}$ (S in Jy).

In determining the resolution bias incompleteness, correct definitions of $h(> \Theta_{\text{lim}})$ and Θ_{lim} could be very important. We checked the robustness of the resolution bias correction by setting different values for α when transforming $h(> \Theta_{\text{lim}})$ to 5 GHz and we changed the definition of Θ_{lim} . In particular we tested the effect of setting a fixed value for Θ_{min} in Eq. (4). In this case Θ_{min} was set equal to $4''$, which roughly represents the typical minimum angular size that is reliably deconvolved at low resolution (see Fig. 9). This latter definition has the effect of increasing the resolution bias correction at the faintest fluxes. The same happens when decreasing the spectral index from 0 to -0.7 . In general, however, significant changes in the normalized counts are seen only for the faintest flux bin. To illustrate such effect at low fluxes, in Fig. 10 we add the point obtained by computing the resolution bias correction c with $\Theta_{\text{min}} = 4''$ and $\alpha = -0.7$ (empty circle at $S = 0.44$ mJy).

The ATEP source counts are compared with previous determinations at 5 GHz. As illustrated in Fig. 10 the ATEP counts are consistent with others reported in the literature and improve significantly the statistics available in the flux range $0.4 - 1$ mJy. The ATEP 5 GHz counts do not show evidence of flattening or slope change down to the survey limit. This

fact is discussed in view of the spectral index properties of the ATEP radio sources in Sect. 7.2.

7.2. 1.4 – 5 GHz spectral index analysis

For the analysis of the 1.4 – 5 GHz spectral index properties of the ATEP radio sources, we extracted from the ATEP 1.4 GHz catalogue (Prandoni et al., 2000b), the list of sources located in the 2×0.5 sq. degr. region surveyed at 5 GHz. Of the 109 1.4 GHz sources found, 89 are catalogued also at 5 GHz, whereas the remaining 20 sources are catalogued only at 1.4 GHz. Similarly we have 22 sources which are catalogued only at 5 GHz, for a total of 131 (1.4 and/or 5 GHz) ATEP sources in the overlapping region. In order to exploit the whole sample of 131 sources for the spectral index analysis, we searched for counterparts of the 42 (20 + 22) sources catalogued only at 1.4 (or 5 GHz) down to a 3σ -threshold (~ 0.2 mJy), by directly inspecting the low resolution 5 GHz (or the 1.4 GHz) ATEP radio mosaics, at the source position. This allows us to probe deeper fluxes than with the 89 ATEP sources catalogued at both 1.4 and 5 GHz ($S_{\text{peak}} > 6\sigma \sim 0.4 - 0.5$ mJy).

The result of this search is reported in Table 4, where, for each source, we list the 5 GHz and/or 1.4 GHz ATEP IAU source name (Columns 1 and 2), the 5 GHz (low resolution) and 1.4 GHz flux density used for the spectral index derivation (Columns 3 and 4), the 1.4 – 5 GHz spectral index with its standard deviation (Column 5).

Table 4. 1.4 – 5 GHz spectral index of ATESP sources.

We notice that flux densities reported in Table 4 are integrated values for resolved sources and peak values for either point-like sources or $< 6\sigma$ detections. For undetected sources $3\sigma_{\text{local}}$ upper limits are provided. In addition, 1.4 GHz flux densities are corrected for systematic effects (e.g. clean bias and

radial smearing), following the recipe derived in Prandoni et al. 2000b (Appendix B).

In summary we have that 118 of the 131 ATESP sources are detected at both frequencies (down to a 3σ -threshold), 5 are detected only at 5 GHz and 8 only at 1.4 GHz.

Fig. 11. *Top:* 1.4 – 5 GHz spectral index vs. 1.4 GHz flux density for the ATEP sample. Only sources catalogued at 1.4 GHz ($S_{\text{peak}}(1.4\text{ GHz}) \geq 6\sigma$) are shown. Open circles with arrows indicate spectral index upper limits due to sources undetected at 5 GHz (the solid line indicates the 3σ detection limit). Horizontal dotted lines show the $\alpha = 0$ and the $\alpha = -0.5$ loci. Circled dots refer to sources displaying a multiple-component/extended radio morphology (either at 1.4 or 5 GHz, either at low or full resolution), typical of AGN-driven radio galaxies. *Bottom:* Spectral index distribution for the same sources shown above. Shaded histogram refer to upper limits. The vertical dashed line indicates the median spectral index value of the sample ($\alpha_{\text{med}} = -0.57$).

Figures 11 and 12 show the 1.4–5 GHz spectral index as a function of flux density, for the 109 sources catalogued at 1.4 GHz and for the 111 sources catalogued at 5 GHz respectively (see top panels). Also plotted are the spectral index distributions at the two frequencies (bottom panels). As expected for higher frequency selected samples, the median spectral index is flatter at 5 GHz ($\alpha_{\text{med}} = -0.40$) than at 1.4 GHz ($\alpha_{\text{med}} = -0.57$) and both samples show a flattening (much more evident at 5 GHz) going to lower flux densities (see Table 5). For $S_{1.4\text{ GHz}} > 4$ mJy, α shows a narrow dispersion around a median value of -0.71 (-0.62 at 5 GHz), as expected for standard synchrotron radio emission. At fainter fluxes, however, almost half (46%) of the sources selected at 1.4 GHz and almost 2/3 ($\sim 63\%$) of the sources selected at 5 GHz show flat spectra ($\alpha > -0.5$), with a significant fraction (29% at 5 GHz) of inverted spectra ($\alpha > 0$).

It is worth noticing that, since the 5 GHz survey has been conducted several years later than the 1.4 GHz survey, flux variability could affect the spectral index derivation for a number of sources. In particular, it could explain the most extreme cases (like ultra-steep and/or ultra-inverted sources). On the other hand, the two ultra-steep sources ($\alpha < -1.3$) present in the sam-

Fig. 12. *Top:* 1.4 – 5 GHz spectral index vs. 5 GHz flux density for the ATEP sample. Only sources catalogued at 5 GHz ($S_{\text{peak}}(5\text{ GHz}) \geq 6\sigma$) are shown. Open circles with arrows indicate spectral index lower limits due to sources undetected at 1.4 GHz (the solid line indicates the 3σ detection limit). Horizontal dotted lines indicate the $\alpha = 0$ and the $\alpha = -0.5$ loci. Circled dots refer to sources displaying a multiple-component/extended radio morphology (either at 1.4 or 5 GHz, either at low or full resolution), typical of AGN-driven radio galaxies. *Bottom:* Spectral index distribution for the same sources shown above. Shaded histogram refer to lower limits. The vertical dashed line indicates the median spectral index value of the sample ($\alpha_{\text{med}} = -0.40$).

ple (see Fig. 11), if real, could potentially be associated to very high redshift galaxies.

The flattening of the radio spectral index going from mJy to sub-mJy flux densities found for the ATEP-DEEP1 sample confirms on a much larger statistical basis (131 sources) previous results obtained for smaller (50 – 60 sources) samples (e.g. Donnelly et al 1987; Gruppioni et al. 1997) and agrees with the finding of many flat/inverted radio spectra in μJy samples (Fomalont et al. 1991; Windhorst et al 1993). On the other hand, it disagrees with a more recent spectral index analysis performed in the Lockman Hole, where the sources are claimed to have steep-spectrum down to 0.2 mJy (Ciliegi et al. 2003). It is worth noticing, however, that the statistics available to the Ciliegi et al. sample at $S_{5\text{ GHz}} > 0.2$ mJy is very poor.

It is interesting to compare the spectral index statistics reported in Table 5 (upper limits are included by using the survival analysis methods² presented in Feigelson & Nelson (1985) and Isobe et al. (1986)) to the one obtained in samples selected at the same frequencies (1.4 and 5 GHz). As mentioned above, a general agreement is found: Fomalont et al.

² Package ASURV Rev. 2.1

Table 5. Spectral index statistics

Flux range	N	α_{mean}	α_{med}	$N_{\alpha > -0.5}$	$N_{\alpha > 0}$
1.4 GHz					
Any flux	109	-0.56 ± 0.04	-0.57	47 (43%)	10 (9%)
$S > 4$ mJy	22	-0.66 ± 0.05	-0.71	7 (32%)	-
$S \leq 4$ mJy	87	-0.53 ± 0.05	-0.53	40 (46%)	10 (11%)
5 GHz					
Any flux	111	-0.28 ± 0.05	-0.40	67 (60%)	28 (25%)
$S > 4$ mJy	13	-0.58 ± 0.06	-0.62	5 (38%)	-
$S \leq 4$ mJy	98	-0.24 ± 0.06	-0.29	62 (63%)	28 (29%)

(1991) report a $\alpha_{\text{med}} = -0.38$ and a $f(\alpha > -0.5) = 60\%$ at fluxes $16 < S_{5 \text{ GHz}} < 1000 \mu\text{Jy}$; while Donnelly et al. (1987) report $\alpha_{\text{mean}} = -0.31 \pm 0.58$, $\alpha_{\text{med}} = -0.42$ and $f(\alpha > -0.5) = 50\%$ at $0.4 < S_{5 \text{ GHz}} < 1.2$ mJy. On the other hand, a somewhat steeper behaviour was found also by Donnelly et al. (1987) at 1.4 GHz: $\alpha_{\text{mean}} = -0.80 \pm 0.49$, $\alpha_{\text{med}} = -0.76$ and $f(\alpha > -0.5) = 22\%$ at $0.5 < S_{1.4 \text{ GHz}} < 3$ mJy, which was interpreted as due to a significantly different composition of the faint radio population depending on the selection frequency.

Indeed the ATESP 1.4 and 5 GHz selected samples have in common only 2/3 of the sources (89/131). This can explain not only the somewhat different spectral properties of the two samples at low flux densities ($S < 4$ mJy), but also why a significant flattening of source counts in 1.4 GHz-selected samples at $S \leq 1$ mJy does not necessarily result in a flattening of the 5 GHz source counts in the flux range covered by the ATESP sample. By assuming as reference $\alpha = -0.53$ (the median spectral index found for the sub-mJy 1.4 GHz selected ATESP sources, see Tab. 5), we expect the flattening to occur at $S_{5 \text{ GHz}} \sim 0.5$ mJy, that is very close to the flux density limit of the 5 GHz ATESP survey.

As a final remark we notice that radio sources with a multiple-component/extended radio morphology, typical of classical AGN-driven radio galaxies, are both shown as circled dots in Figs. 11 and 12. It is evident that such sources are characterized by steep synchrotron radio spectra and are mainly found at mJy flux densities. On the other hand unresolved multiple-component sources can be present also at lower fluxes, where most of the sources could not be successfully deconvolved, due to the poorer deconvolution efficiency (see § 6.2). Higher spatial resolution radio data are needed to assess whether radio emission in sub-mJy flat sources is triggered by active nuclei or large-scale star formation.

8. Summary

We used the ATCA to follow-up at 5 GHz part of the region previously covered by the sub-mJy ATESP 1.4 GHz survey (Prandoni et al. 2000a,b). In particular, we imaged a 1 sq. degr. area where, in addition to the 1.4 GHz information, extensive *UBVRI* deep optical imaging is available (Mignano et al. 2006). The 5 GHz survey was designed to have uniform sensitivity over the entire region observed.

In order to be able to measure the 1.4 - 5 GHz spectral index, we produced 5 GHz images at exactly the same resolution (same size in pixels and restoring beam) as the 1.4 GHz mo-

saics (see Prandoni et al. 2000a). On the other hand, full resolution ($\sim 2''$) mosaics were also produced. As expected, the noise level obtained, $\sim 70 \mu\text{Jy}$, is fairly uniform within each mosaic and from mosaic to mosaic.

We used the low resolution images for the source extraction: we produced a catalogue of 111 radio sources, complete down to $S \sim 0.4$ mJy (6σ). The full resolution information was used to assess **size** and radio morphology of the catalogued sources. A detailed analysis of the source sizes shows that the ATESP 5 GHz sources can be satisfactorily described by the angular size distribution proposed by Windhorst et al. (1990), at least down to $S > 0.7 - 1$ mJy. Below such limit, the high number of sources which remain unresolved even at full resolution prevents us from a reliable analysis. We can only argue that our upper limits ($< 1 - 2''$) are consistent with the result of Fomalont et al. (1991), who find $\Theta < 1.5''$ for sources with $0.06 < S(5\text{GHz}) < 0.8$ mJy. Also consistent is the result of Bondi et al. (2003) who find $\Theta_{\text{med}} = 1.''8 \pm 0.''2$. We notice that Bondi et al. suggest a steeper distribution **than** the one of Windhorst et al. for sources $0.4 < S(1.4\text{GHz}) < 1$ mJy.

We have derived the $\log N - \log S$ relation for the ATESP 5 GHz catalogue. The possible causes of incompleteness at the faint end of the source counts have been taken into account, with particular respect to resolution effects (resolution bias). The ATESP 5 GHz counts are consistent with the counts derived from other 5 GHz surveys and improve significantly the statistics of the counts in the flux range $0.4 - 1$ mJy. The ATESP 5 GHz counts do not show evidence of flattening down to the survey limit.

The 1.4 - 5 GHz spectral index was derived for all the ATESP radio sources present in the 2×0.5 sq. degr. region surveyed at both 1.4 and 5 GHz. A flattening of the spectral index with decreasing flux densities was found, which is particularly significant for the 5 GHz selected sample. At mJy level we have mostly steep-spectrum ($\alpha \sim -0.7$) synchrotron radio sources, while at sub-mJy flux densities we have a composite population, with $\sim 60\%$ of the 5 GHz sources showing flat spectra and a significant fraction ($\sim 30\%$ at 5 GHz) of inverted-spectrum sources. The spectral index flattening of the 1.4 GHz selected sample is somewhat milder, with $\alpha_{\text{med}} = -0.53$ at sub-mJy flux densities against a value of $\alpha_{\text{med}} = -0.29$ found for the 5 GHz sources.

We notice that, when we take into account the spectral index properties of the ATESP 1.4 GHz selected sample, as inferred by our 1.4/5 GHz measurements, we can expect the 5 GHz source counts to flatten at flux densities ~ 0.5 mJy, that is very close to the flux density limit of the 5 GHz ATESP survey. This explains why we do not yet see evidence of such a flattening in the ATESP 5 GHz source counts.

Particularly interesting is the possibility of combining the spectral index information with other observational properties to infer the nature of the faint radio population, with particular respect to flat/inverted-spectrum sources, and assess the physical processes triggering the radio emission in those sources. This kind of analysis needs information about redshifts and types of the galaxies hosting the radio sources. A detailed radio/optical study of our sample is possible, thanks to the extensive optical coverage available to it (see Sect. 2), and is the

subject of the second paper of this series (Mignano et al., in prep.).

Fig. 13. $1' \times 1'$ contour images of most extended sources in the catalogue: 12 sources with deconvolved size (at either low or full resolution) larger than $8''$. Gray lines are for low resolution contours and black lines are for full resolution contours. For each source the contour levels are at 3, 4.5, 6, 10, 20, 50, $100 \times$ the local noise level. Synthesized beams at low and full resolution are shown in the lower left corner.
